Smart /13/, Wood /9/, Morse /1/, and Refs 4, 6, 7), it appears that further analysis and investigation is needed in the case of the acoustic jet.

Previous investigations (Refs. 1, 2) have concentrated largely on directly relating the acoustic phenomena to thrust and have shown among other things that the acoustic jet device is extremely sensitive to open-end edge conditions, and that it is possible to increase the thrust by increasing the amplitude of the forcing vibration. A broad program of further quantitative and qualitative determination of the flow fields in acoustic jets is needed for the attainment of adequate understanding of this special problem and for further insight into the general characteristics of pulsating flow. Pressure surveys, paralleling the thrust investigations, are needed.

A mechanical pulsator was designed and built by the University of Minnesota Mechanical Engineering Staff for use in a broad program of research in pulsatile phenomena employing both mean and instantaneous characteristics. This program was made possible by United Aircraft Research Department support. The pulsator was readily made available for the present work which was proposed as a preliminary phase of the broad program.

The primary objectives were twofold; (1) construction

of the flow patterns and behavior employing tufts, smoke, and dust as flow visualization techniques, and thus establishing, if possible, the salient characteristics of the flow associated with the basic reactor configuration in the available range of amplitude of pulsator vibration; (2) Obtaining mean static and total pressure data, using liquid manometer measurements, showing mean pressure distribution in the basic reactor and jet excited by the highest available (about one inch) amplitude of pulsator vibration.

The work was carried out in the Engines Laboratory of the Mechanical and Aeronautical Engineering Departments of the University of Minnesota, under the guidance of Dr. T. A. Hall. The author wishes to express his appreciation for the use of the pulsator, which was made possible through United Aircraft Research Corporation support, and to express his thanks and appreciation to the following: Dr. T. A. Hall, for his direction and counsel; Professor F. E. Murphy, for his suggestions; and Dr. Professor E. L. Kelly, for his suggestions and assistance.

# SYMBOLS

$p_g$	Gage mean static pressure, inches of water, referred to atmospheric pressure.
$p_o$	Gage mean total pressure, inches of water, referred to atmospheric pressure.
$p_a$	Ambient atmospheric pressure, inches of mercury, absolute.
$t$	Ambient atmospheric temperature, degrees Fahrenheit. Also used for time in seconds.
$T$	Absolute temperature, degrees Rankine. Thrust is lb.
$x$	Distance along resonator axis, in inches, measured from the plane normal to the axis, at the open end of the resonator, towards the closed end (piston).
$-x$	Same as $x$ except measured in the other direction (external).
$z$	General variable for distance along resonator measured from plane of closed end.
$L$	Resonator length in inches.
$\phi$	Angular position in degrees in any plane normal to the resonator axis; referred to a zero line extending from the axis vertically upward; and increasing in a clockwise direction as the observer faces the closed resonator end from the open end. This is used in the tables (see Table VII and subsequent tables through XII) to indicate the position and direction of the probe at the introduction point. Thus, in Table XII, the static wall pressure at the probe introduction point is at the top of the pressure data column for 0° and for 30°, and is at the bottom of the pressure data columns for 150° and for 270°.
$r$	Radial distance from the resonator axis in inches, positive along the line defining $\phi$ ; negative along the line defining $\phi \pm 180^\circ$ .

r <sup>1</sup>	Distance, in inches, measured from the inside resonator wall along a line extending through, and normal to, the resonator axis. Thus it has its largest magnitude at the resonator axis. It is not used negatively.
nr & n	Revolutions per minute of the pulser crankshaft unless reference is to some other mechanism.
c	Piston stroke in inches measured from head-end down center.
l	Crank radius in inches.
u	Center to center length of connecting rod in inches.
θ	Angular position of the pulser crank from head-end dead center.
v	Linear velocity variable.
u	Velocity paralleling resonator axis, positive in direction of positive x.
a	Speed of propagation of a sound wave.
f	Frequency, cycles per second.
ω	Angular velocity, radians per second.

#### Terms Used in Tables

Basic Resonator Configuration. Refers to the basic resonator configuration as described in detail under Apparatus.

Wall Static. Refers to the instrumentation arrangement described, and so referred to, in the section on Apparatus.

Internal Instrument. Refers to the instrumentation arrangement described, and so referred to, in the section on Apparatus.

External Instrument. Refers to the instrumentation arrangement described, and so referred to, in the section on Apparatus.

Square. Used with reference to the open end edge of the separator, it signifies that the tube was cut squarely off in a plane normal to the axis and that the resulting edge was not unduly tapering.

Sharp. Used with reference to the open end edge of the separator, it signifies that the edge was tapered to a sharp edge consistent with the end of the inner wall.

## RELATED THEORY

The elementary theory, concerning the possible resonant modes of vibration in air columns traversed by plane pressure waves or impulses, is well established and appears in most textbooks on sound (Refs. 7, 8). It should suffice to review briefly the theory directly related to the resonator configuration which was used in this work, namely, a circular tube open at one end and closed at the other.

### Single Resonator Theory

Pressure impulses (pulses) in a tube by plane surfaces normal to the axis are generally assumed to propagate as plane waves or waves. These waves reflect from area discontinuities (corners). Upon encountering a plane wall, as a closed end of a tube, they reflect without change of phase. Upon encountering an "aperture", as at the open end of a tube, they reflect with a one-hundred eighty degree change of phase, i.e., compression waves are reflected as rarefaction waves and rarefaction waves are reflected as compression waves. These waves travel at local sonic velocity, or higher with respect to the air particles and depending upon their strength. When the tube length and frequency of vibration are related in such a way that reflected waves return

experiment that a "good connection" is needed. Thus, the generally accepted formula for the fundamental frequency of such a resonator is (p. 1).

$$f = \frac{u}{2(L + 0.6r)} \quad (1)$$

### Illustrative Fire-Stream Diagram

For this also, the action, time interval in the single theory (fire stream), and under the additional assumption that the compressions and rarefactions are weak plane waves produced instantaneously at the fire-stream location of the fire, it is of interest to follow the progress of these compressions and rarefactions in an illustrative fire-distance diagram ("fire stream") such as is shown in Figure 2. The small arrow indicates the direction of the velocity increments  $\Delta u$ , and is equal to  $\Delta u$ , the wave. The circled numbers indicate the strength of the wave in units of  $\Delta u$ . Obviously, having an idea of what enters into the actual situation is that a state of equilibrium is reached when the energy level of the fire stream is higher with the loads, and at this point the waves have reached their maximum strength.

### Piston Motion

The motion of the piston is of interest because it originates the pulse and determines the boundary conditions of the closed end. The pulsator employed in this investigation was designed with a conventional crank-pin and connecting rod linkage with provision for adjusting the piston stroke in the range of zero to several. Thus (ref. 10), the piston displacement from dead-end dead center (-) is:

$$x = r + L - (r^2 - L^2 \sin^2 \theta)^{1/2} - L \cos \theta \quad (2)$$

where  $r$  is the center-to-center length of the connecting rod;  $L$  is the crank radius; and  $\theta$  is the angular position of the crank face measured from center. The approximate piston velocity ( $\dot{x}$ ) in feet per second is:

$$\dot{x} = 0.000307 \pi (\sin \theta + \frac{L}{r} \sin 2\theta) \quad (3)$$

where  $\pi$  is RPM;  $L$  is in inches; and  $r = L/\lambda$ . The approximate acceleration of the piston velocity ( $\ddot{x}$ ) in feet per sec.<sup>2</sup> is:

$$\ddot{x} = 0.000107 \pi^2 (\cos \theta + 2 \frac{L}{r} \cos 2\theta) \quad (4)$$

where the units are as before.

### Additional Wave Theory

Reinforcement of a cumulative effect is taking place at resonance, so that the final level of pulse strength is difficult to predict. If the coordinates are transferred to the new coordinate system, it is evident that the approach velocity of the flow relative to the transverse pulse is lower than that which may be calculated under assumption of the final level of pulse strength and temperature distribution actually is. It is shown in analogous texts that the local velocity of wave propagation is a function of the local absolute temperature, thus (Ref. 15):

$$a = \sqrt{g r M^2} = \sqrt{r p / c} \quad (5)$$

where the units must be consistent.

There are certain fundamental physical differences between compressive waves and explosive waves. Some of these are ordinarily considered negligible when treating well isolated waves, but are of no mean to them dealing with strong waves or the conditions produced by the repetitive passage of a great many weak waves. It may be shown (Ref. 15) that if a finite, continuous, compressive wave is started, such as by a piston moving sinusoidally in a tube, and point of this disturbance, then it

of is a small step wave, such propagates itself at the local speed of sound, relative to the fluid at that point, and will therefore overtake the initial increment of the wave, after a finite time, to form a discontinuity such that the compression takes place practically instantaneously. This must occur because the value of a compression wave is characterized by an increase in entropy and temperature (and thus velocity of propagation) over the unperturbed conditions. The time is needed for this to occur is given by (Ref. 17, p. 17).

$$t = (2/\sqrt{1}) (1/v) \quad (3)$$

where  $v = (dQ/dt)_{\text{all}}$ , the maximum slope of the pressure-volume-distance curve. If the maximum slope of the velocity-distance curve for the piston be taken as a crude approximation of that value, one finds, for the case of one-inch piston strokes and 1005 ft/sec related to a nine foot long resonator, that the time required to form a discontinuity would be approximately 0.009 seconds, while the time required for the pulse to reach the open end of the resonator would be approximately 0.004 seconds so that a discontinuity is not formed. If, if the maximum slope of the velocity-distance curve for the flow over the piston was used as a crude approximation of that value for the piston,

would appear near the open end of the resonator.

The reverse situation is true for an expansion wave. Each succeeding segment of such a wave finds itself travelling in a slightly smaller radius than the segment immediately preceding it, and thus at a slightly lower rate. This expansion wave tends to become less steep and to spread out. There is no natural mechanism for the formation of a discontinuous expansion wave (ref. 18). The approach flow velocity relative to an expansion wave remains an invariant of velocity increases, decrease non-linearly with distance apart a segment.

#### Measurement of Oscillatory Pressures

Special problems arise in connection with the simplest measurements of oscillating pressures. The fluid is essentially flowing in one direction of the resonant transmission system and this is a non-isentropic process involving flow work and accompanying viscous losses. The natural frequency of the instrumentation, if selected, may completely distort the actual picture. The full spectrum are characteristically attenuated, especially, the low.

Attenuation refers to the pressure drop along a tube due to viscous forces (not resonance effects) and is generally calculated on the basis of Poiseuille's law of viscous resistance.

which is given as (Ref. 11):

$$\partial p / \partial x = -(128 / \pi) (\mu' / D^3) Q \quad (17)$$

where  $p$  is the instantaneous pressure at any point in the connecting tube;  $x$  is the distance along the tube measured from the entrance;  $\mu'$  is the mean fluid viscosity;  $D$  is the tube diameter;  $Q$  is the volumetric flow at any point in the tube. Equation (16) is combined with the non-steady, one-dimensional form of the equation of continuity, in Ref. 11, to obtain a solution for values of the loss in real amplitude of pressure for a steady-state pressure measurement device. Simplified variation of the entrance is assumed (about the zero pressure), and it is assumed that the instrumentation has been chosen so as to avoid unwanted resonance effects.

An earlier work (Ref. 12) offers a solution which provides the variation with time, and is perhaps more suited to estimation of the attenuating effect on mean pressure when  $\omega \gg \omega_0$ .

In this case, equation (17) was integrated directly, assuming constant volume flow per unit time, to obtain the pressure drop ( $0 \leq x \leq L$ ):

$$P_1 - P_2 = (128 \mu' / \pi D^3) L Q \quad (18)$$

The log is the primary document in the history of  
the city and the county. It is the  
most valuable of all the records. It is  
the key to the city and county history.

possible piston stroke magnitudes available in the range of 100 to 150 mm. The values of piston stroke used in this investigation were, in mm: 0.254, 0.254, 0.254, 0.254, 0.254. These values included the minimum and the maximum for the apparatus. A single pin bearing connecting rod (overall length, center to center) was connected to a crank shaft. The crank shaft was provided with a guide bearing. The pin, secured at the head end of the crank shaft and fitted into a steel cylinder mounted in an end frame. The piston, connecting rod, crank shaft, and guide bearing were all of aluminum. The piston had two clearance rings in the cylinder and was, and had no provision for sealing against the cylinder wall of the cylinder and filling. The cylinder was fitted with a 1/2 inch diameter (corresponding to the inside diameter of the pressure) was eight inches long. The head was two inches of the cylinder was widened to six inches to provide the pressure taking.

The basic principle of operation, as described in the text and table, refers to the pressure configuration as described in the paragraph. The pressure configuration, Table 1 (22.5 inches long; 2.0 inches wide; 1.5 inches high) was bolted together and sealed positively on three support supports

(See Figure 1). One end was inserted in the pulsator receiver  
studier. The ballast coils were sealed with contact tape which  
was easily removable. Small patches of the same material were  
used to seal orifices which were not in use. The overall length  
of the receiver, measured from the open end to the pump piston  
position (one-inch stroke), was found to be two hundred and  
fourty-two inches, or nearly nine feet. The plastic tube  
ends were square-cut, and in particular, the edge of the open  
end of the receiver was square-cut or blunt. Sixteen orifices  
(0.070 in., drilled with sharp no. 50 drill) were spaced six  
inches apart, in a straight line along the upper surface. These  
were numbered as follows and through aluminum standoffs at the  
open end. The orifice near the open end was at a distance of  
three and one-half inches from the left attachment of the tube.  
Four additional orifices of the same diameter were drilled at  
stations 3, 7, 13, and 17. These, together with the top orifice,  
were given equidistant angular spacing (90° apart). The tube was  
carefully aligned with the axis of the pulsator piston. The  
receiver opening was eight feet from the facing wall and the  
receiver center axis was thirty-four inches from the floor.

The main modification to the basic receiver configuration,  
considered in this work, was that used to investigate the  
effect of a sharp versus a blunt open-end edge (Figure 5). This

(5/16 inch ID). Circular pieces of rubber tubing, approximately fifty-fifty inches long, were used to connect the two Y pipe tubes to liquid chambers. The liquid chambers were of brass

The manometers employed were of the liquid, U-tube type (Figure 1). The one which was used for all the two pressure readings and with the lower chamber in position was the full static manometer. It was a laboratory type, No. 11. The scale was graduated, however, in inches of water. The range was from 0 to fifteen inches with only the last two inches each part of the scale marked. A small three and one-half, least count (0.001 inch), called millimetric water, was used with the lower chamber against the specimen, except for occasional readings at the No. 1 which were off the scale. These manometers could be read to the third decimal place on the vertical scale and to the second decimal place on the horizontal scale. All readings were taken as referred to the top of the scale.

The pressure measurement instrumentation was of three types: (1) Wall Static, used for most of the measurements of static pressure at the chamber wall; (2) Internal Pressure, used for the static and total head pressure transducer mounted inside the chamber; (3) Internal Pressure, used for pressure measurements in the jet.

be obtained. This probe was made by taking a  
length of the 1/2 inch ID, and turning down  
the 1/2 inch ID.

- (2) Another steel probe similar to (1) was made of  
steel tubing. This probe was about one-half  
inch long, turned down to 1/2 inch ID,  
and sixty-degree tapered like probe (1).
- (3) A total head probe was made from brass tubing with  
the same dimensions as (2) except that it was one  
inch in length, overall. The end of this probe  
was again tapered to hexagonal shape, except  
that the angle was 45 degrees. A one-eighth inch  
radius fillet corner, was used at the base of the  
taper. From the end of the probe, the hole in the probe  
was approximately one-half inch diameter, and  
parallel to, the axis of the probe, and  
the probe. This probe was removed from the  
total head probe because of its shape.
- (4) A total head probe was also made from brass tubing, with  
the same dimensions as (2). It was a tube, 1/2 inch  
and turned off with a 45 degree angle, and polished down to  
the shape of a cylinder. A hole was drilled in

The hole of the probe three-eighths of an inch from the end. This hole is three-eighths of an inch in diameter which is only slightly different from the inside diameter of the probe (three-eighths of an inch). This probe has been referred to as a cylinder-type total head probe since it is based on the fact that stagnation occurs at the leading edge of a cylinder placed normal to a steady flow.

The external pressure or static pressure is measured as shown in Figure 4. The probe fitted snugly into a hole leading to a mounting plate in the support frame. It could be slid back and forth along a series of notches on the probe for positioning. Vertical positioning could be made by raising the mounting plate up and down between the two vertical support bars. When positioned vertically, the mounting plate position was fixed by a clamp arrangement. The vertical support bars could be rotated about a vertical axis providing another degree of freedom. The external pressure probes were connected to the probe chamber by a 1/8-inch pipe of outside diameter (7/16 in. ID) and a one-way stop-check.

A description of the probe and its external pressure attachment follows.

# RESULTS AND DISCUSSION

## Flow Characteristics of the Resistor

Values of mass static pressure, mean total pressure taken with the probe opening facing the jet, and mean total pressure taken with the probe opening facing away from the jet, are shown in Figure 1 for a jet velocity of 500 ft/sec. The probe static pressure values were not corrected for the probe losses which would just increase the pressure reading. All values are in terms of the reservoir, i.e., pressure, temperature, etc., but the Mach number is based on the jet velocity.

The total head pressure is also shown in Figure 1, parallel to the wall, opposite the jet, and is based on the region near the jet (about 10 in). A tendency for the "facing-away" pressure to be lower than the "facing-toward" pressure is noted in the lower part of the figure. As a point of interest inside the resistor, this trend is reversed, with the facing-away pressure being higher than the facing-toward pressure. This is due to the fact that the jet velocity is higher in the region near the jet and hence the pressure is higher. The total head pressure is also shown in Figure 1, parallel to the wall, opposite the jet, and is based on the region near the jet (about 10 in). A tendency for the "facing-away" pressure to be lower than the "facing-toward" pressure is noted in the lower part of the figure. As a point of interest inside the resistor, this trend is reversed, with the facing-away pressure being higher than the facing-toward pressure. This is due to the fact that the jet velocity is higher in the region near the jet and hence the pressure is higher.

with increased internal resistance from the open end of the resonator.

The reversal of dominant total head values at the resonator mouth suggests that the air inflow and outflow is truly alternating over the whole open end, and that the air motion is not solely atmospheric total pressure, since it is mostly drawn from the surrounding atmosphere at the inlet, and the air performs the oscillation associated with the total oscillations over a relatively short time. At high frequencies, "the two effects (inflow and outflow of the air as a jet) are of course in reality alternating, and only appear to be simultaneous in consequence of the inability of the eye to follow such rapid changes".

The total head reversal, as a wave front, entered the chamber from the resonator open end, marked the transition point between the atmosphere inside the major portion of the resonator which appears to be primarily oscillatory, the inflow and outflow jet flow which appears to be primarily an external circulation system strongly related to the region of the atmosphere from end. Visual observations (Figure 21) suggested that much of the surrounding air, drawn toward the resonator open end, joined the jet flow from the vicinity of the portion of the system with

centering the resonator. It appeared that this air jet caused a depression and tended to support the jet flow.

The various differences between static and total head values (approximately three and one-half times as large) were just inside the resonator pipe and are indicative of velocities in the order of one hundred twenty-five feet per second. The mean velocity at one foot outside the resonator is indicated as about eighty feet per second, and the mean velocity at a distance of three feet outside the resonator is indicated as about sixty feet per second. These values compare with the velocity of fluid flow in a pipe of eight and one-half feet per second and 0.375 in. piston stroke.

#### Lateral Pressure Gradients

A comparison of the mean static pressure distribution along the wall of the resonator with the radial mean static pressure distribution is shown in Figure 3. The axial gradient is greater than the wall gradient except that considerably lower gradients exist just along the wall as the open end of the resonator is approached. The values are very small all over near the closed end. A sharp reversal of the static pressure takes place just inside the pipe end, which is due to the effect of the edge vortex system. The divergence of the

axial and wall static pressure distributions correlates with the visual observations of greatly increased jet particle lengths near the open end, assuming that the latter are an indication of increased jet molecule path lengths.

Profiles of mean static pressure distribution inside the resonator are shown in Figure 11. These profiles, with the exception of that for Station One, were obtained by adding from two pairs of opposed distributions at each station as a check upon the symmetry of the pressure distribution.

Profiles of mean static and total pressures in the external jet area (horizontal plane), are presented in Figure 12 for distances one-half, two and one-half, and six inches from the open end of the resonator.

Total mean profiles are presented in Figure 13. These profiles appear to be small except in the region near the open end of the resonator.

#### Variation in Mean Static Pressure Distribution with Station Location

The mean static pressure distribution along the resonator wall for various magnitudes of piston stroke is shown in Figure 3. The pressure gradient is seen to coincide with piston stroke, although the original pressure distribution pattern is

retained. The cross plot of pressure versus distance along the channel is shown in Figure 9. It appears that the variation is essentially linear in this range. This agrees with the results of the linear pressure piston effect results presented in Ref. 1 for a flat plate retractor without any modification. The greatest rate of change is positive and is near the closed end, but the local rate of change is negative and is near the open end.

#### Variation in Pressure for a Blunt and Sharp Edge Open-end Retractor Configuration

The difference in wall static pressure distribution along the retractor with blunt and sharp edge open-end retractor configurations is shown in Figure 10. Somewhat lower values were obtained with the tapered edge.

#### Variation in Wall Static Pressure with Frequency of Retractor Length

The variation of wall static pressure distribution along the retractor wall is shown in Figure 11 for various retractor lengths. A cross plot of measured pressure with distance is shown in Figure 12. It is evident that a longitudinal pressure gradient is produced much like the retractor

1-20 1-20

condition was stationary. Test figures, arriving at the speed of the regulator, will be in the range of 100 and feed out the central jet. They produce an oscillated wave of pulsating the low pressure circle flow pattern of the jet as shown in figures 21, 22, and 23, and show the degree of symmetry in the flow.

#### Limitation of Results

The main factor affecting the results obtained was the instrumentation detail with reference to the diameter and length of all tubes and constrictions used in the pressure measurement system. Quantitative evaluation of the data would depend on detailed calculation of the system losses along the lines provided in the discussion of related theory (AFC. 11, 11, 10).

It was found that a basic requirement was the exercise of extreme care with regard to the uniformity of the test equipment at each station. During the course of the investigation, some experimental errors were discovered.

Good reproducibility of results was maintained. The results did not appear to be sensitive to the small variation

## SAMPLE CALCULATIONS

### RESONATOR FREQUENCY:

$$\pi = 2.75 \text{ in.}; L = 107.4 \text{ in.}; t = 88^\circ\text{F (Table I)};$$

$$f = \frac{12 \cdot 1148}{4[107.4 + 0.6(2.75)]} = 31.63 \text{ c.p.s.} = 1898 \text{ R.P.M.}$$

### VELOCITY:

$$h_o = -0.67 \text{ in. H}_2\text{O (Table X, Sta. 1)}$$

$$h_s = -3.68 \text{ in. H}_2\text{O (Table VIII, Sta. 1)}$$

$$V = \sqrt{\frac{2(p_o - p_s)}{\rho}} = \sqrt{\frac{2(64.2)(3.68 - 0.67)}{(12)(0.002378)}} = 116 \text{ ft./sec.}$$

### THRUST:

$$H_a = 29.42 \text{ in. Hg} = 400 \text{ in. H}_2\text{O (Table V)}.$$

$$h_{s(\text{piston})} = h_{sp} = +6.6 \text{ in. H}_2\text{O (Fig. 8, uncorrected)}$$

$$h_{s(\text{open edge})} = h_{se} = -3.6 \text{ in. H}_2\text{O (Fig. 8, uncorrected)}.$$

$$T = p_{sp} \cdot A_p + p_{se} \cdot A_e - p_a \pi(3)^2$$

$$p_{sp} = \text{absolute pressure on piston, lbs/in.}^2$$

$$p_{se} = \text{" " " open-end edge, lbs/in.}^2$$

$$p_a = \text{" " atmospheric assumed acting externally on unit.}$$

$$A_p = \text{piston area} = \pi(2.75)^2 = 23.80 \text{ in.}^2$$

$$A_e = \text{open-end edge area} = \pi(3)^2 - A_p = 4.48 \text{ in.}^2$$

$$T = \frac{62.4}{12 \cdot 144} [406.6(23.8) + 396.4(4.48) - 400(28.28)]$$

$$= 6.06 \text{ lbs.}$$
